ABSTRACT

Background Healthcare workers fighting against the coronavirus disease 2019 (COVID-19) pandemic are under tremendous pressure, which puts them at an increased risk of developing psychological problems. Aims This study aimed to investigate the prevalence of psychological problems in different healthcare workers (ie, physicians, medical residents, nurses, technicians and public health professionals) during the COVID-19 pandemic in China and explore factors that are associated with the onset of psychological problems in this population during this public health crisis.

Methods A cross-sectional, web-based survey was conducted in February 2020 among healthcare workers during the COVID-19 pandemic. Psychological problems were assessed using the Generalized Anxiety Disorder Scale, Patient Health Questionnaire and Insomnia Severity Index. Logistic regression analyses were used to explore the factors that were associated with psychological problems.

Results The prevalence of symptoms of anxiety, depression, insomnia and the overall psychological problems in healthcare workers during the COVID-19 pandemic in China was 46.04%, 44.37%, 28.75% and 56.59%, respectively. The prevalence of the overall psychological problems in physicians, medical residents, nurses, technicians and public health professionals was 60.35%, 50.82%, 62.02%, 57.54% and 62.40%, respectively. Compared with healthcare workers who did not participate in front-line work, front-line healthcare workers had a higher risk of anxiety, insomnia and overall psychological problems. In addition, attention to negative or neutral information about the pandemic, receiving negative feedback from families and friends who joined front-line work, and unwillingness to join front-line work if given a free choice were three major factors for these psychological problems.

Conclusions Psychological problems are pervasive among healthcare workers during the COVID-19 pandemic. Receiving negative information and participating in front-line work appear to be important risk factors for psychological problems. The psychological health of different healthcare workers should be protected during the COVID-19 pandemic with timely interventions and proper information feedback.

INTRODUCTION

The dramatic spread of coronavirus 2019 (COVID-19) pandemic worldwide has caused a tremendous public health crisis.1,2 Across the globe, a greater number of fatalities by COVID-19 have been reported than those by the previous severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome combined, even though COVID-19 has a relatively low death rate.3 However, to date, no effective treatment has been developed to cure people with COVID-19.4 With increasing number of confirmed cases and death counts due to COVID-19, this overwhelming global pandemic poses a great challenge to the local healthcare systems. As the number of patients with COVID-19 grows, increasingly more health resources, including personnel, beds and facilities, are at maximum capacity. With limited resources, people will be under greater pressure and experience greater distress, especially healthcare workers.5-6

To control the transmission of the offending virus, severe acute respiratory syndrome coronavirus 2, and treat people with COVID-19, many medical measures have been implemented in different countries. By 8 April 2020, according to the WHO, 22073 confirmed cases of COVID-19 have been reported among healthcare workers in 52 countries.1 More than 42 000 healthcare workers in China, including physicians, nurses, technicians and public health professionals, from other provinces went to Hubei Province to provide assistance.7 In addition to supporting Hubei, different healthcare workers including physicians, nurses, technicians and public health staff in other provinces were divided into several groups to establish fever clinics, manage individuals with COVID-19 and control the infection among medical staff.8 To ensure the quality of
medical services, several researchers have appealed to the authorities to take the necessary steps for strengthening mental health and wellness for healthcare workers.\textsuperscript{9,10}

Compared with the general population, healthcare workers are facing tremendous pressure from COVID-19, especially those who might be in contact with suspected or confirmed cases, due to the high risk of infection, inadequate protection, loss of control, lack of experience in managing the disease, overwork, negative feedback from patients, perceived stigma, significant lifestyle changes, quarantine and less family support.\textsuperscript{11–13} These factors increase the incidence of psychological problems among healthcare workers, such as fear, anxiety, depression and insomnia, which can negatively affect work efficiency and long-term well-being.\textsuperscript{14,15} During the SARS epidemic, 29\%–35\% of hospital workers suffered from a high degree of emotional distress.\textsuperscript{13} Even several years later, 10\% of healthcare workers still reported symptoms of post-traumatic stress.\textsuperscript{16} Individuals who experienced quarantine or worked in wards for patients with infection were two to three times more likely to have post-traumatic stress symptoms.\textsuperscript{16} Although a few studies have investigated the prevalence of psychological problems among healthcare workers during the COVID-19 pandemic,\textsuperscript{17,18} no study has investigated the distribution of psychological problems among different groups of healthcare workers.

A more comprehensive understanding of psychological burden among different groups of healthcare workers during this period is crucial for providing psychological support, improving mental health support services and strengthening mental healthcare worldwide.\textsuperscript{19} This cross-sectional study investigated the prevalence of psychological problems in different healthcare workers during the COVID-19 pandemic in China and explored the demographics and COVID-19-related and work-related factors that are associated with various psychological problems.

**MATERIALS AND METHODS**

**Study design**

An anonymous cross-sectional study was performed using the social media platform–based (WeChat) survey program Questionnaire Star in February 2020 in China. Healthcare professionals, including physicians, medical residents, nurses, technicians and public health professionals, were invited to voluntarily participate in the self-administered online survey. The detailed flowchart of this study is shown in figure 1. At the beginning of the questionnaire, we informed participants that they would be signing the consent by default if they completed the survey.

**Study sample**

Healthcare workers from different regions throughout China were recruited based on social networks of investigators and research teams, in order to reach a large number of subjects. The participants were contacted via a designated link, which was disseminated through the primary means of communication and social networks of each participant. Those who are not medical professionals, are non-users of WeChat or did not complete the assessment were not involved in this survey. Medical students were excluded in this analysis because most of them do not enter the stage of clinical practice. We analysed the data collected from 16 February to 23 February 2020, at the early stage of the COVID-19 pandemic, until a projected sample size was reached based on estimates of the prevalence of psychological problems during the SARS outbreak.\textsuperscript{13}

**Measurements**

We developed a questionnaire to collect data on demographic characteristics and psychological status of subjects and information about the COVID-19 pandemic. The duration of the questionnaire was approximately 10 min. Demographic data, including age, gender, race, years of education, annual household income, geographical region and occupation, were obtained. We assessed regular exercise and hazardous drinking and smoking by asking the respondents the following questions: ‘Did you engage in physical exercise for 150 min or more per week?’\textsuperscript{20} ‘Did you drink regularly more than 14 units of alcohol (equivalent to six pints of beer or six glasses of wine) per week?’\textsuperscript{21} and ‘Did you smoke 10 or more cigarettes per day for one or more years?’\textsuperscript{22} The respondents responded ‘yes’ or ‘no’.

The Chinese version of the Seven-Item Generalized Anxiety Disorder Scale (GAD-7) was used to measure symptoms of anxiety during the past 2 weeks.\textsuperscript{23} Cut-off points of 5, 10 and 15 were classified as mild, moderate and severe anxiety, respectively.\textsuperscript{24} The diagnostic threshold of the GAD-7 was previously reported to be 10.\textsuperscript{25} We identified depressive symptoms during the past 2 weeks using the Chinese version of the Nine-Item Patient Health Questionnaire (PHQ-9), which has shown high consistency with a diagnosis of major depression based on structured interviews.\textsuperscript{26,27} Cut-off
points of 5, 10 and 15 were classified as mild, moderate and severe depression, respectively. A PHQ-9 score $\geq 10$ was previously reported to have a sensitivity of 88% and specificity of 88% for major depression. A PHQ-9 score $\geq 10$ indicates depression. A PHQ-9 score $\geq 15$ indicates clinical insomnia. 29 GAD-7, PHQ-9 and ISI scores were treated as dichotomous variables in the univariate analysis. We performed unadjusted logistic regression analyses to investigate factors that are associated with anxiety, depression, insomnia and the overall psychological problems. Variables were included in the multiple backward logistic regression analysis if they had p values $<0.05$ in the unadjusted analysis. The results are reported as adjusted ORs with 95% CIs. All of the tests were two-sided. $P<0.05$ was considered statistically significant. SPSS V.20 software was used for statistical analyses.

**RESULTS**

Demographic characteristics

A total of 2285 healthcare workers from 28 province-level regions in China completed the questionnaire, of whom 707 (30.94%) were men and 1578 (69.06%) were women, with an average age of 31.06 years (SD=6.99 years). The participants included medical residents (913; 39.96%), physicians (860; 37.64%), nurses (208; 9.10%), technicians (179; 7.83%) and public health practitioners (125; 5.47%). The respondents’ years of education varied from 11 years to 30 years, with an average of 18.25 years (SD=2.34 years). Among the respondents, 43.46% were from eastern China, 33.74% were from western China, 15.40% were from central China and 5.82% were from northeastern China. The majority of the respondents worked in tertiary hospitals (table 1).

Prevalence of psychological problems in healthcare workers

Table 2 presents the prevalence of anxiety, depression, insomnia and the overall psychological problems in healthcare workers. For anxiety, 46.04% of the healthcare workers had GAD-7 scores $\geq 5$, including 34.44% with mild anxiety and 11.60% with moderate/severe anxiety. The highest prevalence of anxiety symptoms was observed in nurses (51.44%). The lowest prevalence of anxiety symptoms was observed in medical residents (38.99%). For depression, 44.37% of the healthcare workers had PHQ-9 scores $\geq 5$, including 31.55% with mild depression and 12.82% with moderate/severe depression. The highest prevalence of depressive symptoms was observed in public health professionals (48.80%). The lowest prevalence of depressive symptoms was observed in medical residents (40.53%). For insomnia, 28.75% of the healthcare workers had ISI scores $\geq 8$, including 21.97% with subthreshold insomnia and 6.78% with moderate/severe insomnia. The highest prevalence of insomnia symptoms was observed in nurses (33.17%). The lowest prevalence of insomnia symptoms was observed in medical residents (50.82%).

Factors associated with psychological problems

We performed binary logistic regression analyses to identify demographic and relevant contextual factors that are associated with psychological problems (table 3). In the unadjusted logistic regression analysis, several factors...

†GAD-7 score ≥10 indicates anxiety.
‡PHQ-9 score ≥10 indicates depression.
§ISI score ≥15 indicates insomnia.
¶Met the criteria in † or ‡ or §.
GAD-7, Seven-Item Generalized Anxiety Disorder Scale; ISI, Insomnia Severity Index; PHQ-9, Nine-Item Patient Health Questionnaire; ref, reference.
were independently associated with anxiety (GAD-7 score ≥10), depression (PHQ-9 score ≥10), insomnia (ISI score ≥15) and the overall moderate/severe psychological problems.

In the multiple logistic analyses, factors that were independently associated with a higher risk of anxiety included attention to neutral information about the pandemic (OR=1.38, 95% CI 1.04 to 1.83), receiving negative feedback from families or friends who joined front-line work (OR=2.53, 95% CI 1.50 to 4.26), joining front-line work (OR=2.12, 95% CI 1.49 to 3.02) and unwilling to join front-line work if given a free choice (OR=2.57, 95% CI 1.50 to 4.43).

High annual household income (¥100000–¥300000 vs <¥50000, OR=0.64, 95% CI 0.46 to 0.89; >¥300000 vs <¥50000, OR=0.34, 95% CI 0.19 to 0.63) and regular exercise (OR=0.51, 95% CI 0.37 to 0.70) were independently associated with a lower risk of depression. Factors that were independently associated with a higher risk of depression included attention to negative information about the pandemic (OR=2.49, 95% CI 1.48 to 4.18), attention to neutral information about the pandemic (OR=1.50, 95% CI 1.14 to 1.97), receiving negative feedback from families or friends who joined front-line work (OR=2.96, 95% CI 1.73 to 5.06), unwilling to join front-line work if given a free choice (OR=2.38, 95% CI 1.39 to 4.06) and uncertain about joining front-line work if given a free choice (OR=1.47, 95% CI 1.10 to 1.97).

Factors that were independently associated with a higher risk of insomnia included drinking (OR=2.43, 95% CI 1.29 to 4.55), attention to negative information about the pandemic (OR=3.34, 95% CI 1.84 to 6.06), receiving negative feedback from families or friends who joined front-line work (OR=3.47, 95% CI 1.95 to 6.17), joining front-line work (OR=1.90, 95% CI 1.21 to 2.97) and unwilling to join front-line work if given a free choice (OR=3.39, 95% CI 1.86 to 6.17).

Regular exercise (OR=0.62, 95% CI 0.48 to 0.80) was a protective factor against the overall psychological problems. However, drinking (OR=2.06, 95% CI 1.26 to 3.36), attention to neutral pandemic information (OR=1.41, 95% CI 1.21 to 1.78), attention to negative pandemic information (OR=1.81, 95% CI 1.11 to 2.94), receiving negative feedback from families or friends who joined front-line work (OR=2.38, 95% CI 1.46 to 3.87), joining front-line work (OR=1.85, 95% CI 1.35 to 2.54), unwilling to join front-line work if given a free choice (OR=2.36, 95% CI 1.44 to 3.85) and uncertain about joining front-line work if given a free choice (OR=1.49, 95% CI 1.15 to 1.93) were independently associated with increased risk of overall psychological problems (table 4).

**DISCUSSION**

**Main findings**

The present results show that self-reported psychological problems are prevalent in healthcare workers during the COVID-19 pandemic. Moreover, different kinds of healthcare workers exhibited a distinct prevalence of anxiety, depression, insomnia and overall psychological problems. We further identified the possible risk factors associated with psychological problems, including participation in front-line work, attention to neutral or negative information about the pandemic, receiving negative feedback from people who worked on the front-line, and uncertainty or unwillingness to join front-line work and so on. The findings help provide information for psychological interventions among healthcare workers in other countries and religions.

The high prevalence of psychological problems that was found in this study is consistent with recent findings from two other Chinese research studies with relatively small samples.17 32 The prevalence of self-reported symptoms of anxiety, depression and insomnia in these two previous surveys was 44.7%, 50.7% and 36.1%32 and 44.6%, 50.4% and 34.0%,17 respectively. Another study confirmed the severe mental health conditions in healthcare workers and indicated that medical health workers reported more symptoms compared with non-medical health workers.38

In addition, compared with the general population (eg, 34.43% of the general population experienced psychological distress),35 healthcare workers have a much higher risk of psychological problems (eg, anxiety, depression and insomnia) during the epidemic.15 34 35 This may be related to the higher risk of infection on account of being exposed to patients with COVID-19 and tedious work involved in caring for them and reminds us of the importance of providing psychological support to healthcare workers during a pandemic.

Moreover, this study analysed the prevalence of psychological problems in different healthcare workers, including nurses, physicians, medical residents, technicians and public health professionals. Approximately one-third to half of the nurses reported symptoms of anxiety, depression and insomnia. Nurses, mostly women who are more susceptible to mental problems, may have a higher workload and greater risk of direct exposure to patients with COVID-19.36 Moreover, owing to the contagious nature of COVID-19, as a preventive measure, nurses may be separated from their family members to reduce the risk of transmission, and research has shown that worrying about family members may be one of the main sources of stress in nurses, indicating the critical role of community support for nurses’ mental health.37 Similar to nurses, physicians are also under great stress, and nearly half of the physicians reported anxiety and depression. However, majority of the physicians are male and may have a higher acceptance of risk than nurses and have better coping skills.38 39 In this study, we also found a high prevalence of psychological problems in public health professionals and technicians. However, few studies have investigated their mental health during a pandemic, and further research is warranted to provide more evidence. During the COVID-19 pandemic, many medical residents do not directly participate in the care...

†GAD-7 score ≥10 indicates anxiety.
‡PHQ-9 score ≥10 indicates depression.
§ISI score ≥15 indicates insomnia.
¶Met the criteria in † or ‡ or §.
GAD-7, Seven-Item Generalized Anxiety Disorder Scale; ISI, Insomnia Severity Index; PHQ-9, Nine-Item Patient Health Questionnaire.
of patients with COVID-19 (eg, many medical residents may only be on stand-by at home during the COVID-19 pandemic), and thus, they reported less anxiety, depression, insomnia and overall psychological problems. These findings indicate that based on the sociodemographic, occupational and institutional disparities, different psychological interventions should be delivered to healthcare workers.

One interesting finding of this study was that paying attention to negative or neutral information (rather than positive information) about the COVID-19 pandemic and receiving negative feedback from families and friends who joined front-line work were associated with a higher risk of psychological problems. Exposure to a preponderance of negative information about a disaster and misinformation from the media and surrounding people can potentially damage mental health. However, although individuals with psychological disorders might tend to focus on negative information about the COVID-19 pandemic, such information can also have a negative impact on their mental health, which may lead to a vicious circle. In addition, engaging in regular exercise might serve as a protective factor against depression and overall psychological problems, and a higher household income was also found to be protective against depression, which is consistent with previous studies. We also found that hazardous drinking was independently associated with insomnia and overall psychological problems. These results demonstrated the importance of information control and a healthy lifestyle (eg, regular exercise and no hazardous drinking) in reducing psychological problems in healthcare workers.

Another intriguing finding in this study was that healthcare workers’ unwillingness to join front-line work if given a free choice was independently associated with psychological problems, which is consistent with previous studies. The major reason for unwillingness to work on the front-line is lack of confidence in infection control knowledge and skills. Individuals who perceive that they have a limited capacity in such knowledge and skills are more likely to experience psychological problems. Healthcare workers’ knowledge and skills need to be improved so that they are well equipped to cope with infectious disease, and steps should be taken to provide necessary support to reduce the risk of infection and improve the work environment.

Limitations
This study has several limitations. This was a cross-sectional online survey and the sample is not necessarily a well representation. The causal relationships should be interpreted with caution. Although a relatively large number of healthcare workers participated in this study, the limited number of participants in the northeast areas of China might have caused the findings to be underpowered. More studies are needed to explore the longitudinal trajectories of anxiety, depression and insomnia symptoms in healthcare workers during the COVID-19 pandemic in China. Moreover, the number of nurses, technicians and public health professionals who participated in this study was limited, which may limit the generalisability of findings. The results were based on self-reported questionnaires that investigated psychological problems, which might be different from clinical diagnostic interviews.

Implications
The results of this study show the burden of psychological problems among different healthcare workers during the COVID-19 pandemic. The findings suggest that a greater risk of psychological problems may be associated with receiving negative information about the pandemic. Participation in front-line work appears to be an important risk factor for anxiety, insomnia and overall psychological problems. Moreover, depression and symptoms of post-traumatic stress might persist even after such a crisis is over, and might exceed the consequences of the pandemic itself. These findings will help improve our understanding of the influence of pandemics on psychological health among healthcare workers and suggest implementation of steps that go beyond saving the lives of patients with COVID-19—psychosocial interventions and support should be integrated into public health responses to the COVID-19 pandemic, particularly for healthcare workers. Evidence-based psychosocial interventions and support for short-term psychological problems, such as anxiety, depression and insomnia, at the early stage of the pandemic are necessary. Moreover, self-relaxation training, regular exercise and healthy lifestyle should be emphasised. Additional studies should be conducted to explore the long-term impact of the COVID-19 pandemic (eg, depression and post-traumatic stress disorder) and psychosocial interventions to improve mental health.
